Abstract

Central production cross-sections of hard dijets with 2,1 or 0 rapidity gap at Tevatron are analyzed in terms of diffractive (“a la Good-Walker”) and non diffractive fluctuations of the incident particles. The observed large factorization breaking and the unexpected high value of the 2 to 1 gap cross-section ratio are explained in terms of scattering with and between the incident particles.

1. Recent measurements of production of two large transverse momentum jets in the central rapidity region at Fermilab energies [1, 2] revealed a strong breaking of the Regge Factorization between the “no-gap”, “single-gap” and “two-gap” cross-sections. If the presence of the rapidity gap is interpreted as the colour singlet (*cf.* “Pomeron”) exchange and its absence as the octet exchange, Regge factorization appears to be broken if

$$\frac{\Sigma_2}{\Sigma_1} \equiv R_{2/1} \neq \frac{\Sigma_1}{\Sigma_0} \equiv R_{1/0} , \quad (1)$$

where Σ_0 , Σ_1 and Σ_2 denote the cross-sections for “no-gap”, “single-gap” and “two-gap” events, respectively, and $R_{i/j} \equiv \Sigma_i/\Sigma_j$, by definition.

†Address: F-91191 Gif-sur-Yvette Cedex, France; e-mail: pesch@spht.saclay.cea.fr.

Experimentally [1], the ratio $R_{2/1}$ (resp. $R_{1/0}$) in (1) is estimated in practice by the ratio of dijet event rates per unit ξ_p (resp. $\xi_{\bar{p}}$), the fraction of momentum lost by the incident proton (resp. antiproton), measured as a function of x_{Bj} . Averaged over (small) x_{Bj} , the results are quoted to be $R_{2/1} \sim 0.8 \pm 0.26$ for the L.H.S of (1) and $R_{1/0} \sim 0.15 \pm 0.02$ for the R.H.S. [1]. The factorization breaking $R_{1/0}/R_{2/1} \sim 0.19 \pm 0.07$ [1] thus reaches a factor as small as 1 over 5. In itself, the high value of $R_{2/1} = \mathcal{O}(1)$ is also a question to be understood. Our aim is to give a theoretical estimate of these ratios.

In the present note we argue that the origin of these effects is basically the same as that observed in measurements of diffractive (virtual) photon-induced and hadron-induced processes [3, 2]. We show that it can be described in the same framework as done in Ref. [4] as due to the influence on dijet diffractive production of the soft scattering of the diffracted initial particles (protons and antiprotons at Tevatron).

2. Let us recall briefly the argument given in [4] where the (single) diffractive production of two large transverse momentum jets was discussed. Following the idea of Good and Walker [5], one first expands the incident hadron state into a superposition of diffractive (eigen)states.

$$|h\rangle = c_1|\psi_1\rangle + c_2|\psi_2\rangle + \dots \quad (2)$$

A diffractive state is an eigenstate (by definition, in the subspace of states spanned by diffractive interactions) of absorption, i.e. we have

$$T|\psi_i\rangle = \lambda_i|\psi_i\rangle + \omega_i|\phi_i\rangle \quad (3)$$

where $T = 1 - S$ is the absorption operator and thus λ_i is the absorption coefficient¹ of the state $|\psi_i\rangle$. $|\phi_i\rangle$ describes the inelastic states which are at the origin of absorption. They are multiparticle states which do not show any rapidity gap². Unitarity of the S-matrix implies

$$|1 - \lambda_i|^2 = 1 - |\omega_i|^2 = 1 - \sigma_{nondiff}^i, \quad (4)$$

where $\sigma_{nondiff}$ is the non-diffractive cross-section. (4) is a special case of the generic relations for diffraction

$$\begin{aligned} |1 - \lambda|^2 &= 1 - \sigma_{inel} = 1 - \sigma_{nondiff} - \sigma_{dd} \\ 1 - \omega^2 &= 1 - \sigma_{nondiff} = 1 - \sigma_{inel} + \sigma_{dd} \end{aligned} \quad (5)$$

where σ_{dd} is the diffractive dissociation cross-section. Indeed, for a diffractive state, as seen from (3), $\sigma_{dd} = 0$.

¹At high energy λ_i is dominantly real and positive.

²The first term in (3) is usually interpreted as ‘‘Pomeron exchange’’ where no colour is exchanged between $|\psi_i\rangle$ and the target. The second term would then describe all colour exchanges and thus $|\omega_i|^2$ represents the probability of this colour-exchange interaction.

Using (2) and (3), it is not difficult to express the diffractive transitions between different hadronic states in terms of the absorption (λ_n) and expansion (c_n) coefficients:

$$\langle h' | \mathbf{t} | h \rangle = \sum_n \lambda_n (c'_n)^* c_n . \quad (6)$$

The physical content of the expansion (2) and of the formula (6) depends, of course, on the physical meaning one ascribes to the “diffractive” states $|\psi_i\rangle$. Following [4] we could take them as states with a fixed number and transverse positions (in impact parameter space) of partons [6, 7]. In a modern language, we could equivalently consider QCD dipole states [8].

3. We are interested in three³ processes:

$$\begin{aligned} (i) \quad p + \bar{p} &\rightarrow p + (C) + \bar{p} \\ (ii) \quad p + \bar{p} &\rightarrow p' + (C) + \bar{p} \\ (iii) \quad p + \bar{p} &\rightarrow p' + (C) + \bar{p}' , \end{aligned} \quad (7)$$

where (C) denotes a centrally produced system (at rapidity y) of two large transverse momentum jets and a “background” of the soft particles nearby. p' , $(\bar{p}')$ represent the states which have no rapidity gap between the p ($\bar{p}$) and (C) . Thus (i) corresponds to “two-gap” events, (ii) to “single-gap” events and (iii) to “no-gap” events, see Fig.1.

Figure 1: *Diffractive dijets with and without gaps.*

Now we have to write down the expansions of (7) into the diffractive states. Since we are interested in *hard* diffraction, i.e., in the process whose probability is small, we follow [4] and assume that the expansion is quasi-diagonal. Consequently we write

³It will also be useful to consider the process $(ii)^*$ symmetric to (ii) in the interchange of left and right moving projectiles, namely

$$(ii)^* \quad p + \bar{p} \rightarrow p + (C) + \bar{p}' .$$

$$\begin{aligned}
|p\rangle &= |g\rangle + \epsilon|g+D\rangle + \epsilon_P|p+D\rangle \\
|p'+C\rangle &= -\epsilon^*|g\rangle + |g+D\rangle + \epsilon'|p+D\rangle \\
|p+C\rangle &= -\epsilon_P^*|g\rangle - \epsilon'^*|g+D\rangle + |p+D\rangle
\end{aligned} \tag{8}$$

where ϵ, ϵ_P and ϵ' are small (and thus will be kept only up to first order)⁴. Here $|g\rangle$ denote a superposition of diffractive states representing a bunch of *soft* partons (close to their distribution in the left moving proton) and (D) is a superposition of partonic states consisting of a *hard* (*i.e.* small in transverse space) dipole at rapidity y and a number of soft partons with rapidities nearby (this system eventually decays predominantly into two large transverse momentum jets and the background of soft particles).

Using (3) and (8) we thus obtain

$$\begin{aligned}
\langle p|\mathbf{t}|p\rangle &\equiv \lambda_p = \lambda_g \\
\langle p'+C|\mathbf{t}|p\rangle &= \epsilon (\lambda_{(g+D)} - \lambda_g) \\
\langle p+C|\mathbf{t}|p\rangle &= \epsilon_P (\lambda_{(p+D)} - \lambda_g),
\end{aligned} \tag{9}$$

where the transition matrix $\mathbf{t}$ is to be considered diagonal in both rapidity and impact parameter space. All quantities on the R.H.S. are to be understood as linear combinations of the corresponding quantities defined for truly diffractive parton states.

Following [4] we now assume that $\lambda_{(g+D)}$ and $\lambda_{(p+D)}$ for *diffractive states* can be calculated assuming an independent scattering of their components [9], i.e.

$$1 - \lambda_{(g+D)} = (1 - \lambda_g)(1 - \lambda_D); \quad 1 - \lambda_{(p+D)} = (1 - \lambda_p)(1 - \lambda_D). \tag{10}$$

When this is inserted into (9) we have

$$\begin{aligned}
\langle p'+C|\mathbf{t}|p\rangle &= \epsilon \lambda_D (1 - \lambda_g) \\
\langle p+C|\mathbf{t}|p\rangle &= \epsilon_P \lambda_D (1 - \lambda_g).
\end{aligned} \tag{11}$$

4. To obtain the cross-sections $\Sigma_{1,2}$ for one-gap and two-gap events, see (1), we have to square the corresponding amplitudes, sum over the final hadronic states and integrate over the suitable rapidity and impact parameter intervals. In a first stage we shall discuss the differential cross sections $\sigma_{1,2}$, before integration over rapidity and impact parameter variables. For given rapidity y and impact parameter position $\vec{s}$, the summation extends for σ_1 over all states (p') and (C) as the detailed final state is not measured. For σ_2 one sums only over all states of (C) , because the final proton is identified. These differences imply different

⁴The relations between expansion coefficients follow from orthonormality of the states.

averaging procedures for the diffractive states. Taking this into account, we obtain

$$\begin{aligned}\sigma_1(\vec{s}, y) &= \left[|\epsilon(\vec{s}, y)|^2 |\lambda_D(\vec{b}-\vec{s}, Y-y)|^2 \right]_{av} \left[|1 - \lambda_g(\vec{b}, Y)|^2 \right]_{av}; \\ \sigma_2(\vec{s}, y) &= \left[|\epsilon_P(\vec{s}, y)|^2 |\lambda_D(\vec{b}-\vec{s}, Y-y)|^2 \right]_{av} \left| 1 - \left[\lambda_g(\vec{b}, Y) \right]_{av} \right|^2, \quad (12)\end{aligned}$$

where we have explicitly indicated the averaging procedures. $Y, \vec{b}$ are the rapidity and impact parameter distances between the incident particles. At this point one can observe that, as seen from (4), (5),

$$\left[|1 - \lambda_g(\vec{b}, Y)|^2 \right]_{av} = 1 - \left[\omega_g^2(\vec{b}, Y) \right]_{av} = 1 - \omega_p^2(\vec{b}, Y) = \left(1 - \left[\lambda_g(\vec{b}, Y) \right]_{av} \right)^2 + \sigma_{dd}. \quad (13)$$

It is important to remember that - since the averaging concerns only one vertex - σ_{dd} here corresponds to the *single diffractive dissociation in one vertex*. All this implies that

$$\sigma_1(\vec{s}, y) = \left[|\epsilon(\vec{s}, y)|^2 |\lambda_D(\vec{b}-\vec{s}, Y-y)|^2 \right]_{av} [1 - \omega_p^2(\vec{b}, Y)] \quad (14)$$

so that in the following one can omit the index av without running into confusion.

One sees that the formula (12) for σ_2 is not symmetric with respect to the interchange of the projectile and the target. To restore the symmetry we have to require that

$$|\lambda_D(\vec{b}-\vec{s}, Y-y)|^2 = V_P |\epsilon_P(\vec{b}-\vec{s}, Y-y)|^2 \quad (15)$$

where, *a priori*, V_P is a vertex function of $(\vec{s}, y; \vec{b}-\vec{s}, Y-y)$ which must be symmetric with respect to exchange of the corresponding arguments. However, since the L.H.S. of (15) depends only on $\vec{b}-\vec{s}$ and $Y-y$, V_P can depend neither on $\vec{s}$ nor on y . Symmetry implies that it must be a constant, depending only on the internal variables of the vertex.

The formula (15) shows that the two-gap diffractive interaction can be equivalently understood as the elastic interaction of the projectile with a Good-Walker (Pomeron-like) fluctuation of the target.

From (12) and (15) we deduce that

$$\begin{aligned}\sigma_2(\vec{s}, y) &= V_P |\epsilon_P(\vec{s}, y)|^2 |\epsilon_P(\vec{b}-\vec{s}, Y-y)|^2 |1 - \lambda_g(\vec{b}, Y)|^2 \\ &= V_P^{-1} |\lambda_D(\vec{s}, y)|^2 |\lambda_D(\vec{b}-\vec{s}, Y-y)|^2 |1 - \lambda_g(\vec{b}, Y)|^2. \quad (16)\end{aligned}$$

5. We have to discuss now the no-gap events and thus to go beyond the Good-Walker argument, as the latter refers only to diffractive interactions. To this end we observe that the probability of a no-gap event to occur can be written as the product of (a) the probability of fluctuation of the projectile into $|g' + D\rangle$, i.e.

$|\epsilon|^2$, and (b) the probability of *non-diffractive* interaction of the central system (D) with the target, i.e. ω_D^2 :

$$\sigma_0 = |\epsilon(\vec{s}, y)|^2 \omega_D^2(\vec{b}-\vec{s}, Y-y) \quad (17)$$

Since the same argument can also be used by exchanging the roles of the target and projectile we also have

$$\sigma_0 = |\epsilon(\vec{b}-\vec{s}, Y-y)|^2 \omega_D^2(\vec{s}, y) \quad (18)$$

which implies that

$$[\omega_D(\vec{s}, y)]^2 = V |\epsilon(\vec{s}, y)|^2 \quad (19)$$

where V is another vertex function, symmetric with respect to exchange of the corresponding arguments. For the similar reasons as those following Eq.(15) we deduce that it is actually a constant. Thus we finally obtain

$$\begin{aligned} \sigma_0 &= V |\epsilon(\vec{s}, y)|^2 |\epsilon(\vec{b}-\vec{s}, Y-y)|^2 \\ &= V^{-1} \omega_D^2(\vec{s}, y) \omega_D^2(\vec{b}-\vec{s}, Y-y) . \end{aligned} \quad (20)$$

A closer look shows that the vertex functions V and V_P are identical. This can be seen by observing that the cross-section for one-gap events, σ_1 , given in (12), can be also calculated as a product of (a) the probability of fluctuation of the target into $(\bar{p}+D)$, i.e. $|\epsilon_P|^2$, (b) the probability of *non-diffractive* interaction of (D) with the projectile, i.e. ω_D^2 and (c) the probability that no *non-diffractive* interaction of the final antiproton with the projectile took place⁵, i.e. $(1 - \omega_p^2)$ (c.f. (5)). Thus we can write ($\omega_{\bar{p}} = \omega_p$)

$$\sigma_1(\vec{s}, y) = |\epsilon_P(\vec{b}-\vec{s}, Y-y)|^2 \omega_D^2(\vec{s}, y) [1 - \omega_p^2(Y)] . \quad (21)$$

Comparing (21) and (14) we have

$$|\epsilon_P(\vec{b}-\vec{s}, Y-y)|^2 [\omega_D(\vec{s}, y)]^2 = |\epsilon(\vec{s}, y)|^2 [\lambda_D(\vec{b}-\vec{s}, Y-y)]^2 . \quad (22)$$

This equation has a simple physical meaning. It says that the probability of a fluctuation of the projectile into the projectile+gap+D configuration is proportional to the elastic interaction in the projectile-D system, whereas the probability of fluctuation into no-gap configuration is proportional to the non-diffractive interaction in this system. It thus provides the interpretation, in the Good-Walker language, of the “Pomeron exchange” mechanism for gap creation.

From (15), (19) and (22) one sees that indeed the vertex functions V and V_P are identical:

$$V = V_P . \quad (23)$$

⁵Diffractive excitation of the projectile is allowed.

Using now (22) and (21) we obtain⁶

$$\begin{aligned}\sigma_1(\vec{s}, y) &= V |\epsilon(\vec{s}, y)|^2 \epsilon_P(\vec{b}-\vec{s}, Y-y)^2 [1 - \omega_p(\vec{b}, Y)^2] \\ &= V^{-1} |\omega_D(\vec{s}, y)|^2 |\lambda_D(\vec{b}-\vec{s}, Y-y)|^2 [1 - \omega_p(\vec{b}, Y)^2] .\end{aligned}\quad (24)$$

6. Putting together the formulae Eqs. (16),(20) and (24) for the differential cross-sections, and even before evaluating directly the observable quantities mentioned in section 1, it is already possible to get important qualitative hints on the pattern of factorization breaking in diffractive dijet production at the Tevatron.

Considering for instance, the differential⁷ ratios $r_{i/j} \equiv \sigma_i/\sigma_j$, we find

$$\begin{aligned}r_{2/1} &= \frac{|\epsilon_P(\vec{s}, y)|^2}{|\epsilon(\vec{s}, y)|^2} \frac{|1 - \lambda_g(\vec{b}, Y)|^2}{[1 - \omega_p^2(Y)]} = \frac{|\lambda_D(\vec{s}, y)|^2}{|\omega_D(\vec{s}, y)|^2} \frac{|1 - \lambda_g(\vec{b}, Y)|^2}{[1 - \omega_p^2(Y)]} \\ r_{1^*/0} &= \frac{|\epsilon_P(\vec{s}, y)|^2}{|\epsilon(\vec{s}, y)|^2} [1 - \omega_p^2(Y)] = \frac{|\lambda_D(\vec{s}, y)|^2}{|\omega_D(\vec{s}, y)|^2} [1 - \omega_p^2(Y)] ,\end{aligned}\quad (25)$$

where we make use of σ_1^* , (*cf.* footnotes 3, 6) instead of σ_1 in the second row for formal convenience, the qualitative conclusions being unchanged.

Formulae (25) show explicetly that the factorization formula (1) is violated:

$$\frac{\sigma_1^*(\vec{s}, y)}{\sigma_0(\vec{s}, y)} = \frac{\sigma_2(\vec{s}, y)}{\sigma_1(\vec{s}, y)} \times \frac{[1 - \sigma_{nondiff}(\vec{b}, Y)]^2}{1 - \sigma_{inel}(\vec{b}, Y)} .\quad (26)$$

We have expressed the coefficients λ_g, ω_p in terms of their physical interpretation (4),(6). One sees that the factorization violating factor has the same origin as that which was shown in [4] to be responsible for violation of factorization between single diffractive processes at HERA and at FERMILAB. The numerical value may be, however, somewhat different, depending on the size of the cross-section for the *soft* diffractive dissociation in $p\bar{p}$ collisions (giving the difference⁸ between σ_{inel} and $\sigma_{nondiff}$).

Another interesting remark individually concerns the ratios $r_{2/1}$ and $r_{1^*/0}$. Rewriting expression (25) as

$$r_{2/1} = \frac{|\epsilon_P|^2}{|\epsilon|^2}(\vec{s}, y) \frac{1 - \sigma_{inel}}{1 - \sigma_{nondiff}}$$

⁶We can equivalently consider the symmetric σ_1^* of σ_1 by interchange of left and right moving particles, namely

$$\sigma_1^*(\vec{s}, y) \equiv \sigma_1(\vec{b}-\vec{s}, Y-y) .$$

⁷Not to be confused with the integrated ones (1).

⁸In [4] this difference was neglected. If taken into account, the corresponding factor between the HERA and FERMILAB cross-sections should be $1 - \sigma_{nondiff}$ rather than $1 - \sigma_{inel}$. At small impact parameters, however, which are most important for numerical estimates, this difference is expected to be small.

$$r_{1*/0} = \frac{|\epsilon_P|^2}{|\epsilon|^2}(\vec{s}, y) (1 - \sigma_{nondiff}) . \quad (27)$$

In fact, we have to take into account that the specific factor $|\epsilon_P|^2/|\epsilon|^2$ is factorizable since it reflects the probability ratio for a color singlet over an octet to be coupled to the projectile. Hence, we see that the essential factorization breaking factor is concentrated in the second ratio $r_{1*/0}$ and it has the same content as the corresponding factor between the HERA and FERMILAB cross-sections [4]. On contrary, the factorization breaking factor in $r_{2/1}$ is mild, since it depends only on the difference between $1 - \sigma_{inel}$ and $1 - \sigma_{nondiff}$ due to the diffraction dissociation contribution in the total cross-section. These conclusions will be confirmed by the following phenomenological application.

7. To obtain numerical estimates of the cross-sections Σ_i and of the measured ratios $R_{i/j}$, cf. section **1**, one has to perform integration over the rapidity interval y and impact parameters $\vec{b}$ and $\vec{s}$.

For rapidity intervals, the integration is, in some sense, taken into account by the measurement itself, since event densities by unit of ξ are given. hence, even if a full simulation would be welcome to match precisely the experimental conditions, the rapidity dependence is considered to be already integrated out.

The impact parameter dependence has to be taken into account. This is difficult because several necessary elements are not known, so that -at best- only a rough estimate is possible. Only the elastic $p\bar{p}$ amplitude is known with some precision:

$$\lambda_p(\vec{b}, Y) = a_0 e^{-b^2/2B_{el}}; \quad a_0 = \frac{\sigma_{tot}}{4\pi B_{el}} . \quad (28)$$

At $\sqrt{s} = 1800$ GeV, $\sigma_{tot} = 71.71 \pm 2.02$ mb and $B_{el} = 16.3 \pm .5$ GeV⁻² [10], so that $a_0 \approx 0.85$. There is also the inequality (Pumplin bound [12])

$$\lambda_D^2 \leq \omega_D^2 . \quad (29)$$

To simplify the discussion we assume tentatively that the shapes (in impact parameter space) of λ_D^2 and ω_D^2 are similar and take the Gaussian forms for easy integration:

$$[\lambda_D(\vec{s}, y)]^2 = \eta \omega_D^2(\vec{s}, y) = A \exp[-s^2/B_D] . \quad (30)$$

where B_D is the slope in the elastic scattering of the central system (D). Guided by the results from hard diffraction of virtual photons [11], we estimate B_D to be in the region around 4 GeV⁻² .

Using (16), this allows to determine σ_2 . The integration over d^2s and d^2b gives

$$\frac{\sigma_2}{\sigma_0} \equiv R_{2/0} = \eta^2 \left(1 - 2 \frac{a_0}{1 + \zeta} + \frac{a_0^2}{1 + 2\zeta} \right) \quad (31)$$

where $\zeta = B_D/B_{el}$. Using the obvious identity

$$R_{2/1} = R_{2/0}R_{0/1} = \frac{R_{2/0}}{R_{1/0}} \quad (32)$$

one can thus calculate $R_{2/1}$ from (31) and the measured ratio $R_{1/0}$.

The Fermilab measurements [1] give $R_{1/0} \approx 0.15 \pm 0.02$. Substituting all this into (32) and using the measured ratio $R_{2/1} = 0.8 \pm 0.26$ we deduce that for $\zeta \approx 0.25$, $\eta \approx 1$ (with an error of about 30%). Although this value of η is a perfectly acceptable one⁹, it should be noted that it saturates the unitarity limit. More precise data are needed, however, to consider this interesting property as really established.

This result shows two points. First that our analysis can naturally explain a rather large value of the ratio $R_{2/1}$ measured by the CDF coll. This seems to be a rather non-trivial result. As a sort of by-product we obtain the second point, namely the strong violation of the Regge factorization.

To obtain the theoretical value of the ratio

$$R \equiv R_{2/1}/R_{1/0} = R_{2/0}/R_{1/0}^2, \quad (33)$$

one needs additional information about the soft single diffractive dissociation cross-section in one vertex (c.f. Eq. (4)). For a rough estimate we take

$$\langle \lambda_p^2(\vec{b}) \rangle = a_0^2 e^{-b^2/B_{diff}} \quad (34)$$

which is a simplified version of the analysis by Miettinen and Pumplin [7]. From this and (28) we deduce the diffraction dissociation cross-section to be

$$\sigma_{dd} = (\kappa - 1)\sigma_{el} \quad (35)$$

where¹⁰ $\kappa = B_{diff}/B_{el}$. This gives

$$R_{1/0} = \eta \left(1 - 2\frac{a_0}{1+\zeta} + \frac{a_0^2}{1+2\zeta/\kappa} \right) \quad (36)$$

⁹The fact that we can take $\eta \sim \mathcal{O}(1/2 - 1)$ is related to the fact that the central system D contains some soft partons apart from the hard dipole, *e.g.* *inclusive* diffractive production [13]. Therefore we would predict that in an experiment which will measure the "elastic" two jets *e.g.* *exclusive* diffractive production without accompanying soft hadronic radiation [14], one shall expect $\eta \ll 1$ and falling with increasing transverse momentum of the jets.

¹⁰The ratio $\kappa > 1$ *does not imply* that the slope in diffractive dissociation must be larger than in elastic scattering. This was explained already in Ref.[7]. The parameter B_{diff} is responsible for the behaviour of the average of sum of the squares of the diffractive amplitudes (including elastic amplitude) *in impact parameter space*. From this information it is not possible to deduce directly the behaviour of diffractive dissociation channels in momentum transfer. As shown by Ref.[7], although the diffractive dissociation *is* more peripheral in b space than elastic scattering, its slope in momentum transfer is smaller than that of elastic scattering. As explicitly derived and clarified in the parton picture of Ref.[7], the slope in momentum transfer depends strongly on degrees of freedom which are other than the transverse ones and thus *is not given* by the fourier transform of (34) (*cf.* the comparison of Fig. 2 (for $d\sigma/d^2\vec{b}$) and Fig. 5 (for $d\sigma/dt$) in Ref.[7]).

One sees that the ratio R is independent of η and thus completely determined by the value of κ . To estimate κ we observe that the total *soft* diffractive dissociation cross-section is approximately equal to the elastic one. Assuming the approximate factorization between the single-diffractive and double-diffractive cross-sections we can write for the sum of all contributions to the total *soft* diffractive cross-section

$$\sigma_{diff_{tot}}/\sigma_{el} = 2(\kappa - 1) + (\kappa - 1)^2 = (\kappa^2 - 1) \approx 1$$

leading to $\kappa \approx \sqrt{2}$. For $\zeta = 0.25$ this gives $R \approx 4$, in agreement with the experimental value 5.3 ± 1.8 .

8. In conclusion, we have analyzed the factorization breaking observed in dijet diffractive production at Tevatron, using the same framework which allowed to explain the factorization breaking between HERA and Tevatron single diffractive processes. In both cases, the long distance diffractive interactions between the proton and the antiproton are the cause of the factorization breaking mechanisms.

Interestingly enough, the pattern of factorization breaking in this framework is quite dependent of the number of rapidity gaps (“no-gap”, “single-gap” and “two-gap”), in agreement with the experimental findings. The factorization breaking is strong for the comparison between “no-gap” and “single-gap” cross-sections, since it is related to the total $p\bar{p}$ absorption factor (4), while it is weak¹¹ for “single-gap” *vs.* “two-gap” ones, where it is related to the fraction of the inelastic diffraction to the total inelastic cross-section which is small.

Thanks to the identification of a factorization breaking mechanism, an outcome of our approach is the numerical evaluation of the ratios $R_{i/j}$ and in particular $R_{2/1}$ which is found experimentally to be $\mathcal{O}(1)$, that is surprisingly high. With quite reasonable values for the absorption parameters we find results in nice agreement with the data. Stimulating dijet production results, expected coming soon [16] from the Tevatron, Run II, will allow us to perform a more differential analysis of the mechanism we propose.

Note added. While completing this study, the paper Ref. [17] has appeared, treating the same question within the rapidity gap formalism. We note an agreement between the two approaches.

Acknowledgements

Discussions with Dino Goulianos are highly appreciated. A.B. thanks the Theory Department of the Saclay Centre for a kind hospitality. This investigation was supported in part by the by Subsydium of Foundation for Polish Science NP 1/99 and by the Polish State Committee fo Scientific Research (KBN) Grant No 2 P03 B 09322 (2002-2004).

¹¹Note that our derivation gives an interpretation of the empirical “gap probability renormalization” proposed in Ref.[15]. In particular, only little price (see *e.g.* formula (27)) is payed for the formation of a second rapidity gap once the first is present.
